Individual Exam #3: Kinetics, Electrochemistry, and Thermodynamics

1) A galvanic cell is to be constructed using the following half reactions under acidic conditions:

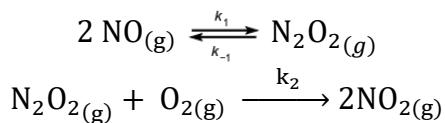

Given that the potentials are measured against the standard hydrogen electrode (SHE) at 298 K and all ions are present at 1 M concentration, what is the maximum possible work output (in kJ/mol) of this cell?

2) Nitric oxide, NO, reacts with oxygen to give nitrogen dioxide, NO₂, a major air pollutant. One possible mechanism is proposed for this reaction:

*Note: k with a negative subscript (*i.e.* k₋₁) represents a rate constant for the reverse reaction.

Mechanism α

a) In a multi-step chemical reaction, an intermediate is a compound that is formed, and then later consumed in a later step. An example of an intermediate is N₂O₂ in mechanism α .

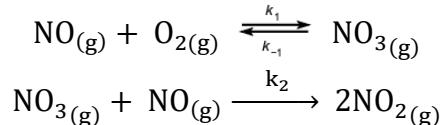

The intermediate is formed at the rate $\frac{d[\text{N}_2\text{O}_2]}{dt}$ and consumed at the rate $\frac{-d[\text{N}_2\text{O}_2]}{dt}$.

If a chemical process involves more than 1 step, and forms at least one intermediate and if at some point the concentration of the intermediate remains constant, the system has achieved what is known as a “steady state.” In other words, under steady state conditions the intermediate is consumed as quickly as it is generated, meaning that $\frac{d[\text{N}_2\text{O}_2]}{dt} = 0$.

Assume that this mechanism is under steady-state conditions. Derive an expression for the rate of formation of NO₂ gas in terms of the concentrations of reactants and not in terms of any intermediate concentrations.

b) A 2nd proposed mechanism for the reaction follows:

Mechanism β

Solve for the rate law of this second mechanism in a similar manner as you did in part (a). Experiments have shown that the reaction is first order in [NO] and first order in [O₂] when the value of k₂ is much greater than k₋₁, and when both mechanisms operate under steady-state conditions. Which mechanism is consistent with these experimental observations?

3) Glucose is an extremely important molecule for humans, and the reactions that turn the glucose from your double cheeseburger into usable energy are among the most important reactions that occur in cells. The first of these reactions is:

a) ΔG° for this reaction at 37°C is +14.3 kJ/mol. What is the equilibrium constant, K_{eq} , for this reaction at 37 °C?

b) The reaction $\text{ATP}_{(\text{aq})} + \text{H}_2\text{O}_{(\text{l})} \rightleftharpoons \text{ADP}_{(\text{aq})} + \text{PO}_4^{3-}_{(\text{aq})}$ is also important in cells, and has $\Delta G^\circ = -31.0$ kJ/mol. Combine these two biological reactions to remove water and unbound phosphate ions, and write the overall reaction.

c) What is K_{eq} for this combined equation?

d) The value of ΔG° at a given temperature is measured under standard state conditions, where the concentrations of all aqueous solutions are 1M. However, the concentrations inside living cells are very different from those assumed under standard state conditions. These are typical equilibrium cellular concentrations of the molecules: [Glucose] = 4.5 mM, [Glucose-6-phosphate] = 5 mM, $[\text{PO}_4^{3-}] = 4.8$ mM, [ATP] = 8 mM, [ADP] = 10 mM. Calculate ΔG (in kJ/mol) for this reaction using the typical concentrations reported here and 37°C.

e) At 37°C, the standard enthalpy change associated with the original reaction (Glucose + $\text{PO}_4^{3-} \rightleftharpoons \text{Glucose-6-phosphate} + \text{H}_2\text{O}$) is -8.3 kJ/mol. What is the standard entropy change (in $\frac{\text{J}}{\text{mol K}}$) of this reaction at 37°C? The standard change in free energy, (ΔG°), is given in part (a).
